ABSTRACT

cRab: A Novel Clustering Score using Clustering with Rivals and Buddies for Unsupervised Learning

Allen Choi

We present a novel clustering score approach relying on a method that classifies pairs of points as either ”rivals” or ”buddies”, constructing a score for a given number of clusters. We then present results demonstrating the properties of this metric on datasets with no clusters.

Keywords: Clustering. Unsupervised Clustering. Score. Machine Learning.

ACKNOWLEDGMENTS

I'd like to first thank my amazing Mom and Dad for providing me so much emotional support over these past half a decade at Cal Poly. Without them, I don't know how I would have gotten through college.

But without a doubt, in regards to my statistical knowledge and skills I have no one else to thank but the amazing Statistics faculty at Cal Poly, who have always been patient, understanding, and kind.

Also a thank you to Andrew Kerr for providing a quarto template: https://github.com/Wander03/CalPolySTAT-thesis-template.

Chapter 1

THE PROBLEM AND WHAT'S BEEN TRIED

1.1 Motivation

Unsupervised clustering algorithms such as K-Means and hierarchical clustering are commonly used today when the number of clusters in a given dataset is not known beforehand, differentiating it from supervised clustering. Kodinariya (2013) presents the most common approaches used, such as the elbow method and Silhouette score. However, even with these scores there are often disagreements and caveats. For example, the elbow method sometimes presents itself as having no elbow, and the definition of an "elbow" is sometimes ambiguous (we need a source for this later). There are also cases where the scores don't necessarily agree, causing confusion in what score to believe.

```
data <- data.frame(rbind(
  cbind(rnorm(50, -5), rnorm(50, -5)),
  cbind(rnorm(50, 0), rnorm(50, 0)),
  cbind(rnorm(50, 5), rnorm(50, 5))))

res <- lapply(c(1:7), function(i) {
  WCSS <- kmeans(data,
                 centers = i, nstart = 10)$tot.withinss
  return(data.frame(i = as.vector(i),
                    WCSS = as.vector(WCSS)))
})
bind_rows(res) |>
```

```r
  ggplot(aes(x = i, y = WCSS)) +
  geom_point() +
  geom_line() +
  theme_minimal() +
  scale_x_continuous(breaks = 1:7)
```

```r
ggplot(data = data, aes(x = X1, y = X2)) +
  geom_point()
```

```
data <- data.frame(rbind(
  cbind(rnorm(50, -1), rnorm(50, -1)),
  cbind(rnorm(50, 0), rnorm(50, 0)),
  cbind(rnorm(50, 1), rnorm(50, 1)),
  cbind(rnorm(50, 2), rnorm(50, 2))))

res <- lapply(c(1:7), function(i) {
  WCSS <- kmeans(data,
                 centers = i, nstart = 10)$tot.withinss
  return(data.frame(i = as.vector(i),
                    WCSS = as.vector(WCSS)))
})
bind_rows(res) |>
  ggplot(aes(x = i, y = WCSS)) +
  geom_point() +
```

```
  geom_line() +
  theme_minimal() +
  scale_x_continuous(breaks = 1:7)
```

```
ggplot(data = data, aes(x = X1, y = X2)) +
  geom_point()
```

We present the cRab algorithm, which utilizes random subsampling of a dataset in order to determine the optimal number of clusters for an unsupervised clustering algorithm.

There will probably be lots of citations here for many articles or even software like R (R Core Team, 2025). (Ben-Hur, Elisseeff, & Guyon, 2001). (Jaeger & Banks, 2023). (Kuhn & Wickham, 2020). (Hvitfeldt & Bodwin, 2025). (Wickham et al., 2019).

Chapter 3

COMPUTATIONAL DETAILS

3.1 Matrix Stacking

3.2 Algorithm Construction

The main principle of our algorithm works off of is the fact that subsamples of a dataset should still capture the overall clustering structure, which is also echoed in the paper from Ben-Hur (2002). This means that given two distinct points and their cluster assignments across resamples, the clustering assignments should be consistent. For example, two points that are far away from each other should consistently not be in the same cluster, and two points that are close together should consistently be in the same cluster, even across resamples.

A "clustering assignment matrix" for each resample is then needed, where for points i and j we have a value of 1 in the matrix if they belong to the sample cluster, -1 if not, and 0 if either point was not in the resample.

After we have n matrices, we then reduce the matrices, taking the mean with respect to each index pair, ignoring zeroes. We then receive a final "mean matrix" of size m x m, where m is the number of observations in the dataset.

3.3 Score Construction

To illustrate the construction of the final score given this mean matrix, we use the penguins dataset in R with three known species and scaled bill length and flipper lengths.

The distribution of values inside the mean matrix after running the algorithm on the penguins dataset, using K-Means and k=2

(replace with code that generates this later)

(replace with code that generates this later)

(Also remove the images folder later)

Figure 2: The distribution of values inside the mean matrix after running the algorithm on the penguins dataset, using K-Means and k=3

We see that from Figures 1 and 2 that the distribution of values inside the mean matrix changes depending on the number of clusters set beforehand in the K-Means algorithm, albeit slightly. For k = 2, there are a small number of points around the value of 0, which indicates that these specific points are ones who are changing "allegiances" often, meaning that they switch from being "buddies" (being in the same cluster) and to being "rivals", (not being in the same cluster).

Then, to make a final score taking all this into account, we decided to vectorize this matrix, then taking the absolute value and getting the sum of squared distances from 1. This is in order to heavily penalize values that are farther from 1.

3.4 Distribution of Ones and Neg Ones

3.5 Speeed and Memory Scaling

Chapter 4

NULL DISTRIBUTION

4.1 Null Distribution of Scores

It is also interesting information to see what the distribution of scores looks like when there are no clusters in the dataset. This is so that our scores can be adjusted depending on this "null distribution", also allowing us to get a degree of evidence for a given k and other parameters.

Figure 4.1: Distribution of Scores on a Random p-Dimensional Normal Distribution, Faceted by Resample %

We see in the above figure that the resample proportion has a significant impact on the distribution of scores, where the variability and mean of scores over many simulation runs is dependent on the resample proportion. The scores also tend to be higher, scaling with

p-dimensions, with a decreasing score distribution as k increases. Notably, all these scores look symmetrically distribution around their mean, with respect to each k.

4.2 Null Distribution over Resamples

```
`summarise()` has grouped output by 'factor(k)'. You can override using the
`.groups` argument.
```

Table 4.1: Variances for 20% Resample Calculation

factor(k)	factor(prop_resample)	var
2	0.2	0.1347830
3	0.2	0.1471547
4	0.2	0.1285054
5	0.2	0.1161971
6	0.2	0.1133949

Chapter 5

CONCLUSION

On the penguins dataset, we use 100 resamples and a resample proportion of 80% wih the k-Means algorithm and a given k, using again the scaled bill length and flipper lengths in our dataset.

(i guess this should also go in the analysis portion??)
